

SYNCHRONISATION OF RESONANCES WITH THRESHOLDS

D. V. Bugg¹

Queen Mary, University of London, Mile End Rd., London E1 4NS, UK

Abstract

The mechanism by which a resonance may be attracted to a sharp threshold is described with several examples. It involves a threshold cusp interfering constructively with either or both (i) a resonance produced via confinement, (ii) attractive t - and u -channel exchanges. More generally, it is suggested that resonances are eigenstates generated by mixing between confined states and long-range meson and baryon exchanges.

1 Introduction

Many examples are known where resonances lie close to sharp thresholds. Table 1 lists several. There is a simple explanation for this effect. The rapid opening of a threshold causes a dispersive cusp at the threshold, generating attraction there. This attraction can capture a nearby resonance.

Examples	Threshold (MeV)
$f_0(980)$ and $a_0(980) \rightarrow K\bar{K}$	991
$f_2(1565) \rightarrow \omega\omega$	1566
$X(3872) \rightarrow \bar{D}(1865)D^*(2007)$	3872
$Z(4430) \rightarrow D^*(2010)\bar{D}_1(2420)$	4430
$Y(4660) \rightarrow \psi'(3686)f_0(980)$	4666
$\Lambda_c(2940) \rightarrow D^*(2007)N$	2945
$P_{11}(1710), P_{13}(1720) \rightarrow \omega N$	1720
$K_0(1430) \rightarrow K\eta'$	1453

Table 1: Likely examples of resonances locked to threshold cusps.

A resonance denominator may be written

$$D(s) = M^2 - s - \sum_j \Pi_j, \quad (1)$$

where M is the resonance mass and the last term is summed over channels:

$$\text{Im } \Pi_j = g_j^2 \rho_j(s) \text{FF}^2(s); \quad (2)$$

¹email: d.bugg@rl.ac.uk

g_j are coupling constants, ρ_j are phase space factors and $FF(s)$ is a form factor in the amplitude (which appears squared in the width of the resonance). Amplitudes are analytic functions of s , so $\text{Im } \Pi_j(s)$ is accompanied by a real part given by the dispersion integral

$$\text{Re } \Pi_j(s) = \frac{1}{\pi} P \int_{s_{\text{thr}}}^{\infty} ds' \frac{\text{Im } \Pi(s')}{s' - s}, \quad (3)$$

where P denotes the principal value integral and s_{thr} is the value of s at threshold. Indeed, $\text{Im } \Pi(s)$ itself originates from a contour integral around the pole at $s' = s$. The dispersive term $\text{Re } \Pi(s)$ is equivalent to evaluating the loop diagram for the open channel, e.g. $\pi\pi \rightarrow KK \rightarrow \pi\pi$.

Figure 1: $\text{Re } \Pi_{KK}(s)$ and $g_{KK}^2 \rho_{KK}(s)$ for $f_0(980)$, normalised to 1 at the peak of $g_{KK}^2 \rho_{KK}$.

Fig. 1 illustrates the s dependence of $\text{Im } \Pi(s)$ and $\text{Re } \Pi(s)$ for $f_0(980)$ at the KK threshold. For this channel, $\rho_{KK} = 2k_{KK}/\sqrt{s} = \sqrt{1 - 4m_K^2/s}$. The form factor is evaluated assuming a Gaussian source in r , which gives (in amplitude)

$$FF = \exp \left[-\frac{1}{6} \left(\frac{kR}{0.197321} \right)^2 \right], \quad (4)$$

where k is the momentum of kaons in their centre of mass in GeV/c and R is in fm. For Fig. 1, FF^2 is taken to be $\exp(-3k^2)$, corresponding to a radius $R = 0.84$ fm. Results depend fairly weakly on this radius. Note, however, that some form factor is required to make the dispersion integral converge, since $\rho \rightarrow 1$ as $s \rightarrow \infty$.

The peak in $\text{Re } \Pi(s)$ corresponds to an effective attraction peaking at threshold. If short-range attraction or meson exchanges generate a resonance nearby, the cusp can lock the resonance close to threshold.

The effectiveness of the cusp as an attractor is studied in Ref. [1] using $f_0(980)$ as an example, and taking M , $g_{\pi\pi}^2$ and g_{KK}^2 from values found by BES for $J/\Psi \rightarrow \phi\pi^+\pi^-$ and ϕK^+K^- [2]. If the g^2 are fixed at BES values and M is varied, there is a pole for all values of M in the range 500 to 1100 MeV. For M between 800 and 1100 MeV, the pole is always within 50 MeV of the KK threshold, demonstrating that the threshold can move the pole a long way from M .

In addition to the cusp effect, there is a further source of attraction to the opening threshold. The deuteron has a long-range wave function $\psi \propto \exp(-\sqrt{M'Br})$, where M' is

the NN reduced mass and B is the binding energy. For a resonance like $f_0(980)$, the wave function extends to ∞ when $B \rightarrow 0$, i.e. at the threshold. The total energy contains a kinetic energy term $\nabla^2\psi/2M'$, and potential energy must overcome this zero-point energy to make a resonance. The curvature $\nabla^2\psi$ of the wave function is a minimum when the wave function extends to ∞ .

Törnqvist [3] gives a formula for the KK component in the $f_0(980)$ wave function, which can be written

$$\psi = \frac{|q\bar{q}q\bar{q}\rangle + \sum_i [(d/ds)\text{Re}\Pi_i(s)]^{1/2} |K\bar{K}\rangle}{1 + \sum_i (d/ds)\text{Re}\Pi_i(s)}. \quad (5)$$

Integrating over the line-shape of the resonance, at least 60% of ψ^2 is KK ; for $a_0(980)$ the corresponding figure is 35%.

Figure 2: (a) the line-shape of $f_0(980)$, (b) its Argand diagram.

Fig. 2 shows the line-shape of $f_0(980)$ and its Argand diagram. Note that the cusp effect at the KK threshold is very strong, so that the resonance is far from a Breit-Wigner of constant width. The width 40-100 MeV for $f_0(980)$ quoted by the PDG refers to the full-width at half-maximum. For $f_0(980)$, $g_{\pi\pi}^2 = 165$ MeV and for $a_0(980)$, $g_{\eta\pi}^2 = 221$ MeV. These are comparable with other resonances such as $f_2(1270)$. In Fig. 2(b), the amplitude turns sharply through 90° at the KK threshold as $ig^2\rho$ changes from real values below threshold to imaginary values above.

Further algebra for the cusp is given in [1]. If one writes $\text{Re}D(s) = M^2 - s + g^2m(s)$, a power series expansion near threshold gives

$$m(s) - m(s_{thr}) = -(2/\pi)\rho^2 + \dots \quad \text{above threshold} \quad (6)$$

$$m(s) - m(s_{thr}) = -\sqrt{4m_K^2/s - 1} - (2/\pi)v^2 + \dots \quad \text{below threshold} \quad (7)$$

where $v = 2|k|/\sqrt{s}$. The first term in the latter expression is the usual Flatté term for the analytic continuation of ρ_{KK} below threshold. The next term in the expansion shows that the cusp is symmetrical to first order in $|\rho|^2$ around the threshold. The term $(-2/\pi)v^2$ may be rewritten $(2/\pi)(4m_K^2 - s)/s$. Note that this term resembles the term $M^2 - s$ in the expression for $D(s)$. Consequently M and g_{KK}^2 are strongly correlated when fitting experimental data; the BES group gives the correlation coefficients. It is important to have data on the KK channel to break the correlation between parameters.

2 Other examples

2.1 $X(3872)$

Fig. 3(a) shows that the cusp due to the $\bar{D}D^*$ threshold is too broad to account for the line-shape in the latest Belle data, Fig. 3(b). A resonance or bound-state is required, as argued by Braaten and collaborators [4] and Hanhart et al [5]. The $\bar{D}D^*$ peak observed 3.5 MeV above the $\bar{D}D^*$ threshold may be fitted by folding the line-shape of $X(3872)$ with $\bar{D}D^*$ phase space, as shown in Fig. 3(c).

Figure 3: (a) $m_{\bar{D}D^*}$ and $\rho_{\bar{D}D^*}$ for $X(3872)$; fits to Belle data [6] for (b) $X(3872) \rightarrow \rho J/\Psi$ and (c) $X(3872) \rightarrow \bar{D}D^*$.

The $X(3872)$ could be a $c\bar{c}$ state which lies fortuitously close to the $\bar{D}D^*$ threshold and has been captured by it. There is however an $X(3940)$ reported by Belle in $\bar{D}D^*$, though with only 24 events above background. Confirmation is important. If all the high energy groups could pool their data and determine the spin-parity, a value $J^P = 1^+$ for $X(3940)$ would require that $X(3872)$ is a molecule. However, alternative possibilities are $J^P = 0^-$ and 2^- , i.e. $\bar{D}D^*$ P-wave states.

2.2 $Z(4430)$

A candidate for an exotic resonance is observed in $\psi'(3686)\pi^\pm$ by Belle at the $D^*(2010)\bar{D}_1(2420)$ threshold, with a width consistent within errors with that of $D_1(2420)$. It can easily be fitted as a resonance. However, it has many de-excitation modes, e.g. $\bar{D}D^*$ and $\bar{D}^*D^*$ and can also be fitted within errors purely as a threshold cusp [1]. The fit done this way is shown in Fig. 4(a) and the Argand diagram in Fig. 4(b). Telling the difference between a cusp and a resonance requires interference with other components in the Dalitz plot.

Figure 4: (a) Fit with a non-resonant cusp to Belle data for $Z(4430)$: (b) Argand diagram.

2.3 $f_2(1565)$

The $f_2(1565)$ is definitely resonant. Crystal Barrel data on $\bar{p}p \rightarrow 3\pi^0$ trace out the phase as a function of mass [7]. A sharp peak appears in $\pi\pi$ decays at 1565 MeV and also in VES data on $\eta\pi^+\pi^-$ [8], both due to the cusp at the $\omega\omega$ threshold. In the $\omega\omega$ channel, a reasonable form factor reproduces the peak observed at 1640 MeV by both GAMS and BES [9]. The $f_2(1640)$ cited by the PDG is simply the $\omega\omega$ decay mode of $f_2(1565)$ [10]. Incidentally, the $f_2(1430)$ of the PDG may also be explained by an interference between $f_2(1270)$ and $f_2(1565)$ [7].

2.4 $\eta(1405)$ and $\eta(1475)$

These are probably two decay modes of a single resonance, $\eta(1440)$. The $\eta(1475)$ appears in $KK\pi$ data, mostly as KK^* , but with a small contribution from $K(K\pi)_S$. The KK^* decay has $L = 1$, hence a dependence k^3 on momentum in this channel. For the central mass of $K^*(890)$, the KK^* threshold is at 1390 MeV and the KK^* phase space increases rapidly with mass. When one allows for KK^* phase space, the 1475 MeV peak may be fitted with a resonance at 1440 MeV.

The $\eta(1405)$ (or $\eta(1415)$ if one takes Crystal Barrel data [11]), appears in $\eta\pi\pi$. This decay mode may be explained by KK^* decay to $KK\pi$, followed by KK rescattering through $a_0(980)$ above the KK threshold. This signal is seen clearly in DM2, Mark III and BES I data on $J/\Psi \rightarrow \gamma(KK\pi)$. The BES I data are fitted simultaneously to $\eta\pi\pi$ data through the $\eta\pi$ decay of $a_0(980)$ [12]. A full analysis requires inclusion of the strong dispersive effect due to the opening of the KK^* channel.

2.5 $Y(4660)$

Guo et al make a strong case for relating this peak to the $f_0(980)\Psi'(3686)$ threshold [13]. They include the dispersive threshold effect.

2.6 Wider thresholds

A full treatment of $a_1(1260) \rightarrow \rho\pi$ and $\sigma\pi$ requires inclusion of the dispersive effect of opening channels. Likewise, $a_2(1320)$ is affected by the opening of the $[\rho\pi]_{L=2}$ channel. In both cases, a Breit-Wigner resonance of constant width is a first approximation. The $f_0(1370)$ was originally fitted as a Breit-Wigner of constant width, but in more detail its parametrisation (and particularly its elasticity) is sensitive to the opening of the $\sigma\sigma$ and $\rho\rho$ thresholds [7]. A similar analysis of $a_0(1450)$ is in progress.

The exotic $\pi_1(1600)$ has been convincingly confirmed at Meson08 by new Compass data on the $\rho\pi$ channel. At lower mass, there are claims for an additional $\pi_1(1405)$. An analysis of these data including the opening of the $b_1(1235)\pi$ and $f_1(1285)\pi$ thresholds is needed to distinguish between a resonance and threshold cusps.

3 What are σ , κ , $a_0(980)$ and $f_0(980)$?

Jaffe [14] proposes to interpret these states as a nonet due to $SU(3)$ $3 \otimes \bar{3}$ states made up of $q\bar{q}$ and $\bar{q}q$ pairs. There is evidence for diquark interactions experimentally and in Lattice Gauge calculations so there is probably some element of such pairs in the wave function. However, there are disagreements with observed decay branching ratios [15]. The ratio $\Gamma[f_0(980) \rightarrow KK]/\Gamma[a_0(980) \rightarrow KK]$ is predicted to be 0.93, but is experimentally 2.15 ± 0.4 and the ratio $\Gamma[f_0(980) \rightarrow \eta\eta]/\Gamma[f_0(980) \rightarrow \pi\pi]$ is also at least a factor 3 less than predicted. The obvious explanation is a substantial KK component in the wave function. More serious is that the ratio $\Gamma[\kappa \rightarrow K\pi]/\Gamma[\sigma \rightarrow \pi\pi]$ is at least 6 standard deviations higher than predicted. The broad κ is only just resonant and falls apart easily.

There are at least three reasons to believe that this nonet is driven largely by meson exchanges. Firstly, Caprini et al. [16] successfully predict $\pi\pi$ phase shifts and the σ pole from the Roy equations; these equations include crossed channels exactly and therefore depend entirely on meson exchanges except for subtractions for scattering lengths. Secondly, Janssen et al. successfully predicted $f_0(980)$ and $a_0(980)$ on the basis of meson exchanges [17]. Thirdly, the model of Rupp and van Beveren successfully accounts for the entire nonet with a single coupling constant and $SU(3)$ coefficients [18]. It finds all four states arise from the continuum, i.e. from non-confined states. An interesting detail of the model is that the movement of the poles can easily be traced as a function of the coupling constant. The $a_0(980)$ is *not* attracted to the $\eta\pi$ threshold because of the Adler zero nearby; this Adler zero is built into the model. Instead it settles close to the KK threshold, because the Adler zero in this channel is distant, at $s = m_K^2/2$.

I shall adopt the view that this nonet is largely driven by meson exchanges. We know that meson exchanges also account for features of t - and u - channel peaks fitted to Regge exchanges throughout the intermediate (few GeV) mass range. My conclusion is therefore that meson exchanges combine with short-range gluonic attraction to form all or most of the resonances other than the σ nonet. The evidence that thresholds attract resonances is consistent with this picture. Oset, Oller and collaborators have found [19] they can predict a number of states purely from meson exchanges as ‘dynamically driven’ resonances, e.g. $\Lambda(1405)$ and $a_1(1260)$. Likewise, Hamilton and Donnachie found in 1965 [20] that meson

and baryon exchanges have the right signs to help generate P_{33} , D_{13} , D_{15} and F_{15} baryons.

Let us carry this argument a step further. Suppose contributions to the Hamiltonian are H_{11} from confined gluons and H_{22} from meson and baryon exchanges. It is almost inevitable that there will be mixing between these two sources, and there is experimental evidence for such mixing for $f_0(1370)$ [7]. Then the eigenvalue equation is

$$H\Psi = \begin{pmatrix} H_{11} & V \\ V & H_{22} \end{pmatrix} \Psi, \quad (8)$$

where V describes mixing. The Variational Principle ensures the minimum value of E is the eigenstate. The stronger of H_{11} and H_{22} gets pulled down. For σ , κ , $a_0(980)$ and $f_0(980)$, long-range forces operate through mesonic S-waves and are stronger at low masses than confinement, which leads to $\bar{q}q$ P -states near the mass of $f_2(1270)$. Otherwise, most non- $q\bar{q}$ and non- qqq states are pushed up and become too broad to observe. There is a close analogy with molecular physics and the formation of the covalent bond in chemistry. There is a cooperative effect between confinement and s - and t -channel exchanges in forming the ground-state.

Valcarce, Vijande and Barnea have made an interesting study of mixing between diquark and tetraquark configurations [21], though they do not specifically take the cusp effect into account. They find that tetraquark configurations all lie higher than diquark configurations if they ignore attraction between diquark pairs. There must be some short-range repulsion between like quarks due to the Pauli principle, as in the short-range repulsion in nucleon-nucleon physics. This repulsion plays a crucial role in preventing nuclear matter from collapsing (and maybe for mesons and baryons too).

Acknowledgements

I wish to thank Prof. G. Rupp and Prof. E. van Beveren for extensive discussions. Use of their model led to important insight into the way poles move near a threshold. I also wish to thank Dr. Y. Kalashnikova for illuminating comments on the Flatté formula.
